Received August 8, 2008

Solid copper(I) cyanide occurs as extended one-dimensional chains with interesting photophysical properties. To explain the observed luminescence spectroscopy of CuCN, we report a series of computational studies using short bare and potassium-capped [Cu(CN)]_{n+1} \(^{-} \) (n = 1, 2, 3, 4, 5, and 7) chains as CuCN models. On the basis of TD-DFT calculations of these model chains, the excitation transitions in the UV spectrum are assigned as Laporte-allowed \( \pi \rightarrow \pi \) transitions from MOs with Cu 3d\(_{x^2-y^2}\) and CN \( \pi \) character to empty MOs with Cu 4p and CN \( \pi^* \) character. Transitions between the HOMO (3d\(_z\)) and LUMO (Cu 4p and CN \( \pi^* \)) are symmetry forbidden and are not assigned to the bands in the excitation spectrum. The emission spectrum is assumed to arise from transitions between the lowest triplet excited state and the ground-state singlet. The lowest energy triplet for the model networks has a bent structure due to distortions to remove the degeneracies in the partially occupied MOs of the linear triplet. The S\(_0\)−T\(_g\) gap for the bent triplet chains is consistent with the emission wavelength for bulk CuCN.

Vol. 48, No. 1, 2009 10.1021/ic801509t CCC: $40.75 © 2009 American Chemical Society Published on Web 11/24/2008
of CuCN, the chains are strictly linear (X–Cu–X and Cu–X–X = 180.0°) and all chains are parallel to one another. Metal–metal interactions are common for Cu(I) compounds; such contacts are typically judged by comparison to the sum of two Cu van der Waals radii, 2.8 Å. However, the nearest Cu···Cu distances in low- and high-temperature forms of CuCN are ca. 3.09 and 3.78 Å, respectively. When CuCN is reacted with simple amines (L), the resulting CuCN–L products are 1D chains in which Cu is 3- or 4-coordinate. Bridging diamine ligands cross-link CuCN chains to form 2D or 3D networks. In many cases these networks are penetrated by independent CuCN chains which thread through the pores in the network.

As indicated above, copper(I) cyanide is a luminescent material, showing a broad excitation feature in the near UV and intense emission at the UV/vis borderline (λ_max = 392 nm). Surprisingly, CuCN luminescence has remained essentially unstudied to date. Studies in aqueous solution by Stevenson have shown photoluminescent behavior in [Cu(CN)2]−. UV photoexcitation of this anion leads to an interesting range of behaviors. The primary fate of singlet [Cu(CN)2]−* is electron ejection. However, competing with this process is intersystem crossing, producing a triplet state. The resulting triplet species may undergo electron ejection or react with [Cu(CN)2]− to form an excimer. In the presence of certain nucleophilic species, such as halide ions or amines, [Cu(CN)2]−* reacts to form exciplexes. A number of possible photophysical causes for luminescence in Cu(I) complexes are recognized. These include metal to ligand charge transfer (MLCT), halide to ligand charge transfer (XLCT), metal-cluster-centered (CC) transitions, single-metal-centered (MC) transitions, and ligand-centered (LC) transitions. Since cyanide is the only ligand in CuCN, XLCT is obviously not a valid option, and transitions of the LC type may also be ruled out since cyanide has a large band gap. The absence of close Cu···Cu contacts argues against CC transitions in CuCN. Nevertheless, even though CC behavior is unlikely in the case of CuCN itself, a number of CuCN–amine networks contain Cu···Cu distances of < 2.8 Å. Transitions of CC nature should not be completely ruled out in these cases.

Elimination of XLCT, LC, and CC phenomena leaves the MC transition and MLCT as possible photophysical sources of luminescence behavior in CuCN. MC transitions are dependent only on the metal orbitals, while MLCT is modulated by the ligand orbitals. Therefore, the question is as follows: What role does cyanide play in the donor and

acceptor states associated with CuCN luminescence? In the current study, we sought to determine the relative importance of MC, specifically \(3\text{d} \rightarrow (4\text{p}, 4\text{s})\), and MLCT contributions in the observed luminescence behavior in CuCN using density functional theory (DFT) and time-dependent DFT (TD-DFT). The latter is an economical method for determining electronic transitions in chemical systems with an accuracy that often rivals the highest level ab initio methods.\(^{11}\) TD-DFT has been applied to a number of extended \(\pi\) systems\(^{12-16}\) and luminescent transition-metal complexes\(^{17}\) with notable problems describing CT states.

Theoretical Methods

Models of the copper(I) cyanide chains were optimized using Gaussian 03\(^{18}\) at the DFT level using the SVWN,\(^{19}\) BLYP,\(^{20,21}\) BP86,\(^{22,23}\) HCTH/407,\(^{23}\) and mPW1PW91\(^{24}\) exchange-correlation (xc) functionals. The copper atoms were represented by the Ermler–Christiansen relativistic effective core potential (RECP) basis set\(^{25}\) modified to include the 4p contractions of Couty and Hall.\(^{26}\) Basis sets for the carbon and nitrogen atoms were the split-valence triple-\(\zeta\) plus polarization functions (TZVP) representations of Dunning.\(^{27}\) The potassium atoms were represented by the Hay–Wadt RECP basis set.\(^{28}\) The excitation spectrum of the model chains was obtained using TD-DFT to generate all transitions to singlet states of less than 5.2 eV (5.4 eV for the \(n = 1\) chain). Optimizations and TD-DFT calculations of selected models were also performed using an extended basis set in which the Cu and K basis sets were uncontracted, a set of \(f\)-type polarization functions were added to Cu, and diffuse functions were added to all atoms except K (BSII).

Results and Discussion

Geometry Optimization. In this study, short bare anionic and potassium-capped chains of CuCN are used to model the electronic structure of the solid-state material. These chains are constructed such that all Cu(I) ions are coordinated by two cyanides \((\text{Cu}_{n}\text{(CN)}_{n+1})\) and constrained to cylindrical symmetry in the ground state \((D_{\infty h}\) and \(C_{n\infty})\). For the K-capped models, the counterion is added to each end of the chain to maintain a symmetric environment and to neutralize the negative charge of the \([\text{Cu}_{n}\text{(CN)}_{n+1}]^{-}\) complex ions.\(^{29}\) The latter prevents underestimation of the electron binding energy known for anions within DFT, but may shift the excitation energies to shorter wavelengths due to the overall positive charge. Potassium was selected as the counterion because it is commonly used as a mineralizing agent for CuCN.

The fully symmetric isomers of the odd K-capped CuCN chains \((K_{2}[\text{Cu}_{n}\text{(CN)}_{n+1}])^{+}, n = 1(5^{3}8, 5(5^{8}), 7(7^{8}))\) with the carbon end of all cyano groups oriented toward the center copper were optimized using five xc functionals: SVWN, BLYP, BP86, HCTH/407, and mPW1PW91 (Table 1 [BLYP only] and Supporting Information Table 1). The

geometries of the analogous bare \([\text{Cu}_n(\text{CN})_n+1]^-\) anions were calculated in the BLYP functional only (Table 1) and are generally similar to those of the K-capped cations. With each functional, the Cu–C bond distances to the central copper are longer than those of the outer coppers by \(\sim 0.02\) Å due to the symmetrical environment around the central metal. The Cu–C, Cu–N, and C–N distances for the asymmetric copper centers are generally similar with the exception of the mPW1PW91 model for which the distances for the terminal cyano are slightly longer. The local density approximation (SVWN) generally produces bond distances to the formally positive copper and potassium ions that are 0.03–0.06 Å shorter than those obtained by the other functionals. The Cu–C and Cu–N distances for BLYP, BP86, HCTH/407, and mPW1PW91 functionals are comparable to the experimental Cu–X bond distances (HT, 1.870 Å, 6 LT, 1.82–1.87 Å). The C–N distances are longer than those in the linear HT phase (1.12 Å) and comparable to the distances in the LT phase (1.145–1.178 Å). In comparison to the BLYP results, the C–N distances in the mPW1PW91 functional and the distances around the copper center for the BP86 functional are slightly shorter than the BLYP values.

The disorder in the X-ray structures of the CuCN network allows for no definitive pattern in the orientation of the alternating cyanide groups. The geometries of the

[photoluminescence of 1-D copper(i) cyanide chains]
unique isomers$^{30}$ of the bare anionic and K-capped (Cu(CN)$_2$) and (Cu$_4$(CN)$_3$)$_x$ chains were calculated at the BLYP level for comparison to those of the fully symmetric isomers (Table 2). Isomers are labeled by the direction of the cyanide group within the chain (Chart 1): R for the CN orientation and L for the NC orientation. There are three unique isomers for $n = 1$ chain ($I_{RL} \equiv 1$ \([N≡C−Cu−C≡N]−\), $I_{LR} [C≡N−Cu−N≡C]−$, and $I_{RR} = I_{LL} [C≡N−Cu−C≡N]−$). The symmetric isomer $I^K$ having the normal carbon linkage to the central copper is $\sim$20 kcal/mol lower in energy than $I_{RL}$ for which nitrogen bonds to the metal (isocyanide). The Cu–N distances in this isomer are shorter (1.835 Å) and the terminal N–K distances are longer (2.815 Å) than those of $I^K$. The isomer with asymmetric linkages, $I_{RL}^K$, lies $\sim$10 kcal/mol above $I^K$. In this case, the Cu–C and Cu–N distances (1.853 and 1.857 Å, respectively) are shorter than those of either of the symmetric isomers. Although these distances are similar, the C–K distance is $\sim$0.15 Å longer than the N–K distance (2.817 Å versus 2.645 Å). The geometries and energies of the bare anion isomers of $I$ are similar to those of the K-capped system (Table 2). On the basis of the preceding observations, it can be reasoned that the higher energy of the LR and RR isomers is those with asymmetric coordination of copper centers in the chain.

Orientation of the cyanides, a situation which is difficult to determine from the X-ray data since defects may appear at different sites in the chains, leading to disorder.

The geometries of the even-numbered bare anionic and K-capped CuCN chains $[\text{Cu}((\text{CN})_n)_2]^− (n = 2$ and 4) were optimized at the DFT/BLYP/BSI level for the isomers with terminal normal linkage of the cyanides only. The bond distances for the single isomer of the $n = 2$ chain ($2 \equiv 2_{RLL} = 2_{RRL}$) and the four unique isomers of the $n = 4$ chain (4 $\equiv 4_{RRRLL} = 4_{RLRLR} = 4_{LRRLR} = 4_{RRLLL} = 4_{RRRR}$) are similar to those for the odd chains. As for the odd chains, there is a preference for asymmetric coordination spheres for all of the copper centers but one. Isomers 4 and $4_{RRRLL}$ are 1.5 kcal/mol below the two isomers having two copper with normal cyanide linkages (Table 2).

Excitation Spectra. The UV/vis spectra of the fully symmetric bare and K-capped $[\text{Cu}((\text{CN})_n)_2]^−$ chains were simulated by TD-DFT using both pure (BLYP, BP86, HCTH/407, and SVWN) and hybrid (mPW1PW91) xc functionals. Analysis of the transitions shows that the dominant bands (oscillator strength $>0.1$, Table 3 (BLYP only) and Supporting Information Table 2) are the Laporte-allowed transitions between MOs of $\pi$ symmetry (Figure 2). Other Laporte-allowed transitions ($\sigma−\sigma$ and $\delta−\delta$) have oscillator strengths at least 1 order of magnitude lower than those of the $\pi−\pi$ transitions. For the $n = 1$ chain, the pure xc functionals (BLYP, BP86, HCTH/407, and SVWN) produce a single high-intensity band (230–240 nm) within the range of the calculation. This band is consistent with the observed $\lambda_{\text{max}}$ for the UV spectrum of $[\text{Cu}((\text{CN})_2)_{1}]^−$ in solution (234 nm).$^{31}$ For the mPW1PW91 xc functional, no transition with an oscillator strength above 0.1 is obtained for the $n = 1$ chain at wavelengths longer than 220 nm. However, the pattern produced for 3K is similar to the results of pure functionals, but shifted to shorter wavelengths by 30–50 nm (Supporting Information Table 2).

The single band for $I$ and $I^K$ predominantly consists of contributions from transitions from the occupied $3\pi_g$ MO (HOMO – 2) to the empty $4\pi_g$ MO (1, LUMO; $I^K$, LUMO + 2). These are the highest occupied and lowest unoccupied $\pi$-type MOs. The band for $I^K$ also includes lesser contributions from transitions from $3\pi_g$ to $5\pi_g$ (LUMO + 4) and $7\sigma_u$ (HOMO – 3) to the $10\sigma_u$ (LUMO + 1). This band has previously been assigned as MLCT,$^{32}$ but the present calculations show a significant amount of metal and cyano character in both MOs (Figure 2). The character of these MOs may explain why the excitation bands derived from the hybrid mPW1PW91 functional are consistently lower than those of the pure functionals. Hybrid functionals generally outperform pure functionals because CT often occurs between MOs that are localized on different parts of the molecule,$^{11}$ as is often true for MLCT bands in d$^0$ TM complexes.$^{17}$ In each of the model CuCN chains, the donor and acceptor MOs are delocalized over the length of the

---

(30) The number of possible isomers is $2^{n+1}$, where $n + 1$ is the number of copper centers in the chain.

chains such that extended polyenes and polyynes are a better analogy. Within these species, pure functionals often give results that are similar to or better than those of hybrid functionals as long as the excitations are not CT in nature. In addition, the error for the longest wavelength transition results in comparison to B3LYP for the Q bands of chlorophyll and the S bands of zeaxanthin, a xanthophyll.13b

In Table 3, BLYP Wavelengths (nm) and Oscillator Strengths (f) for π−π Transitions (TD-DFT) and Adiabatic S0−T Gaps (nm) for Bare Anionic and K-Capped Symmetric Chains [Cu,(CN)nx]− (n = 1, 2, 3, 4, 5, 7) 2) and 15π (HOMO −3) to 16π (LUMO +2) for 4K. In each of these cases, the donor MO has antibonding character between the Cu 3dz AO and CN π bonds and the acceptor MO has bonding character between the Cu 4p AOs and the CN π* fragments. Additional bands arise from transitions to/from π MOs lying lower in energy than these occupied MOs or higher than these unoccupied MOs. For example, for 3K the second intense line (240.6 nm) results from excitation from 6πg (HOMO −6) to 7πg (LUMO + 3) and the third (238.6 nm) from the 6πg (HOMO −3) to 8πg (LUMO + 4) transition. The lower energy occupied MOs are generally antibonding between the Cu 3dz AOs and the CN π fragments, although some low-energy MOs such as 5πg for 5K (Figure 2) show bonding interaction between copper and carbon. The higher virtual MOs are generally bonding combinations of the Cu 4p AOs and CN π* and include contributions from the K 4p MOs as an artifact of the capped models.

From these data, we can see that, as the chain length becomes longer, the longest wavelength transition for the K-capped chains approaches an asymptotic value of 300 nm, short of the experimental λmax by ~40 nm. The intensity of the line, based upon the oscillator strength, also increases as the wavelength increases, mirroring the extinction pattern in the experimental spectrum. For example, the transition lines for 7K are shown in Figure 3 with their intensities as calculated spectral absorbances. The approach of the calculated spectra to an asymptotic value is expected by analogy to the extended π systems of polyynes.16 However, the limiting value is approached more quickly for the K-capped CuCN chains than for polyyne oligomers, for which a limit has not been reached at 24 carbon atoms. For the bare anionic chains, additional bands are also obtained as the chain length increases, but these do not approach an asymptotic value.

Table 3. BLYP Wavelengths (nm) and Oscillator Strengths (f) for π−π Transitions (TD-DFT) and Adiabatic S0−T Gaps (nm) for Bare Anionic and K-Capped Symmetric Chains [Cu,(CN)nx]− (n = 1, 2, 3, 4, 5, 7)

(33) Bayse, C. A. Unpublished data. These results also show a significant dependence of the excitation energy upon the basis set (BLYP, 8.18 (6-31G*), 7.65 (TZVP), 7.85 (cc-pVTZ) eV; B3LYP, 8.51 (6-31G*), 17 7.99 (TZVP), 8.18 (cc-pVTZ) eV).

not approach an asymptotic value for the model chain lengths calculated. For 7, the long-wavelength \( \pi - \pi \) transitions also decrease in intensity from a maximum at the 278.8 nm band (Table 3). The transition between the highest occupied and lowest unoccupied \( \pi \) MOs is calculated to occur at \( \sim 460 \) nm with an oscillator strength of 0.03. Of the two model types, we believe the K-capped chains provide the better overall representation of solid-state CuCN because the pattern in the line intensities and the convergence to a limiting wavelength are consistent with the excitation spectrum in Figure 11A in ref 3c. The fact that the limiting wavelength is found at energies higher than those from experiment can be attributed to the overall positive charge of the chain models. The errors in these gas-phase models may also be attributed to the lack of intermolecular interactions necessarily present in the solid state.

Note that the TD-DFT calculations do not predict a significant contribution to the excitation spectrum from the HOMO–LUMO transition. The HOMOs are metal-centered MOs of \( \sigma \) or \( \sigma_g \) symmetry consisting of the in-phase combination of sd\(_z^2\) hybrid AOs. For the bare anions, transitions from these MOs to the \( \pi \)-type LUMOs are symmetry-forbidden and the oscillator strength of the HOMO–LUMO transition is zero. The LUMOs for the K-capped chains are the asymmetric combination of potassium 4s AOs (\( \sigma_u \)) such that the HOMO–LUMO transition is both symmetry-allowed (\( \sigma - \sigma \)) and Laporte-allowed (\( g - u \)), but TD-DFT assigns small oscillator strengths to these transitions. For example, the HOMO–LUMO transition for \( 3^K \) has an oscillator strength 2 orders of magnitude lower than that of the highest energy \( \pi - \pi \) transition. The LUMO and LUMO + 1, the symmetric K 4s combination, as well as the transitions to these MOs, are artifacts of the K-capped model.

Luminescence excitation in Cu(I) has variously been described as arising from MC or MLCT transitions. Let us consider how these descriptions harmonize with the relevant MOs described above. As shown in Figure 2, copper components of the highest occupied \( \pi \) MOs are largely 3d\(_{xz}\)/3d\(_{yz}\), while those of cyanide are essentially \( \pi \)-bonding. The lowest unoccupied \( \pi \) MOs may be described as Cu 4p\(_x\)/4p\(_y\) and cyano \( \pi^* \). Therefore, the transition between these orbitals can be regarded as MC (3d \( \rightarrow \) 4p) or MLCT (3d \( \rightarrow \pi_{CN^*}\)). However, it can also be seen as LMCT (\( \pi_{CN} \rightarrow 4p\)) or even as ligand-centered (\( \pi_{CN} \rightarrow \pi^*_{CN}\)), although this latter description is probably the least reasonable. Nevertheless, it is probably most useful to regard the excitation in CuCN as involving a combination of \( \pi \) symmetry MC and CT components or simply as an intrachain \( \pi - \pi \) transition. Since electrons are excited from occupied MOs with antibonding character between the d\(_{xz}\) Cu AOs and the \( \pi \) CN fragments to unoccupied MOs with bonding character between the Cu p AOs and \( \pi^* \) CN fragments, we may expect to find Cu–cyano bonding strengthened upon excitation, while C≡N bonding would be weakened.

**Emission Spectra.** The emission spectrum of CuCN is assumed to arise from transition from the lowest excited-state triplet to the ground state. Lifetime studies of soluble

---

**Figure 2.** MO diagram for \( 1^K \), \( 2^K \), and \( 3^K \). The LUMO and LUMO + 1 are artifacts of the K-capped chains and do not occur in the bare anionic chains.
Cu(I)—cyano species have suggested that emission is usually a phosphorescence phenomenon.\textsuperscript{8,31,32} We assume that the triplet forms through intersystem crossing from the photo-excited singlet states and do not model this process explicitly. For the K-capped chains 1\textsuperscript{K}, 3\textsuperscript{K}, and 5\textsuperscript{K}, adiabatic S–T gaps were determined using the optimized geometries (DFT/BLYP) of the lowest triplet state in the D\textsubscript{abh} and C\textsubscript{2v} point groups. Vertical S–T gaps calculated by a TD-DFT calculation generating the triplet excited states are generally similar to the linear adiabatic S\textsubscript{0}–T gaps.

For 1\textsuperscript{K}, the lowest energy linear triplet lies 4.83 eV above the ground state and is energetically equivalent to emission of a 257 nm photon. The unpaired electrons occupy the 3\pi\textsubscript{g} (3e) and 4\pi\textsubscript{u} (1e) MOs, linking this excited state to the lowest energy transition (232.2 nm, 4\pi\textsubscript{u} → 3\pi\textsubscript{g}) calculated by the TD-DFT calculation. Because the partially occupied 4\pi\textsubscript{u} MO has Cu–C bonding and C–N antibonding character, the central Cu–C and C–N distances are slightly shorter (1.868 Å) and longer (1.187 Å), respectively, than the ground-state singlet values. Vibrational analysis shows that this species has a single imaginary frequency which characterizes it as a transition state for bending of the linear chain. On the basis of these results, the C\textsubscript{2v} geometries of the chains were determined under the assumption that, upon excitation of an electron to a degenerate MO, the structure will relax via some distortion. The optimized structure of the lowest C\textsubscript{2v} triplet state (b\textsubscript{2}) shows that distortions are localized around the central copper center where the chain is bent by 97.8° and the Cu–C distances are elongated by 0.14 Å relative to those of 1. The C–N and N–K bond distances are slightly longer than in the ground state. Significant distortions are also found in the optimized structure of the triplet state of the [Au(SCN)\textsubscript{2}]\textsuperscript{−} dimer assumed to contribute to the luminescence properties of K[Au(SCN)\textsubscript{2}].\textsuperscript{35}

The bending of the chain is consistent with a distortion to remove the degeneracies of the partially occupied 3\pi\textsubscript{g} and 4\pi\textsubscript{u} MOs, which decompose as b\textsubscript{2} + a\textsubscript{2} and a\textsubscript{1} + b\textsubscript{1} in C\textsubscript{2v} symmetry (Figure 4). The relaxation of the triplet geometry reduces the energy gap to the ground state by ~1 eV and shifts the wavelength of the predicted emission to 330 nm. The bent structure also concentrates the spin density on the central copper center (1.368), with some spin density found on the carbons of the central cyanide groups (0.271). The spin for the linear triplets is also predominately found on the central copper atom (1.07); however greater spin distribution is seen throughout the chain, especially through the entire central cyanide ligands (C, 0.153; N, 0.183). Both the linear and bent structures are well-represented by triplet densities with very little spin contamination (S\textsuperscript{2} = 2.002).

The triplet states for 3\textsuperscript{K} and 5\textsuperscript{K} lead to similar features in the optimized structures (Figure 5), with the exception that the linear triplets are minima on their respective potential energy surfaces. The linear S\textsubscript{0}–T gaps shift to longer wavelengths due to the smaller band gap observed for longer chains. The bent C\textsubscript{2v} S\textsubscript{0}–T gaps are found at slightly higher energies relative to the ground state. The bent triplet was also determined for the lowest energy n = 3 chain, 3\textsubscript{RRRLK}. The optimized structure of the 3\textsuperscript{A}′ state features a bend in the chain at a terminal copper with little distortion in the rest of the chain. The S\textsubscript{0}–T gap for this structure is slightly smaller than that of 3\textsuperscript{K} (329.6 nm). In both chains, the overall length of the chain is reduced in the C\textsubscript{2v} triplet by 1.5 Å, and the bend in the chain results in a significant displacement of the central copper center from its position in the linear chain as defined by the positions of the potassium centers (see Figure 5).

The apparent bending of the triplet excited state is relevant to what is known about the photoexcitation of [Cu(CN)\textsubscript{2}]\textsuperscript{−} in solution. Horváth and Stevenson have both noted the tendency of [Cu(CN)\textsubscript{2}]\textsuperscript{−} to form exciplexes (e.g., with halide or amine ligands) or excimers in solution.\textsuperscript{8,31,32} It may well be that the bending of the excited-state triplet lies behind the apparent bending of the triplet excited state.

exciplex or excimer formation. Such bending would open up a coordination site, easing formation of an additional metal covalent interaction with an incoming nucleophile. In the case of the solution-phase excimers, this nucleophile would be another \([\text{Cu(CN)}_2]^–\) anion which could form a bridge through the cyano group; however, cuprophilic Cu···Cu interaction cannot be ruled out.

Although the \(S_0 – T\) gaps for the model chains are similar to the emission wavelength of CuCN, comparisons to solid-state CuCN are more difficult due to concerns over the flexibility of the chains, the available space in the crystalline lattice, and interchain interactions. Crystal structures of CuCN–L networks suggest that bending in the extended chains can be facile. For example, independent CuCN chains threaded through CuCN–diamine networks show cyano–Cu–cyano bond angles ranging from nearly 180° to less than 150°.\(^{3b, c, 10e, 10f, 10l}\) No doubt these angles are affected by packing effects, but they clearly reveal significant flexibility in CuCN chain bond angles. In addition, as-yet-unpublished results in our laboratory show that CuCN spontaneously absorbs liquid- or vapor-phase amines at room temperature to form CuCN–L phases on the surface of the solid. The known CuCN–L phases can be recognized via X-ray diffraction.\(^7\) These phases show significant bending of the cyano–Cu–cyano angle due to formation of 3- and occasionally 4-coordinate Cu. Therefore, it appears that CuCN bending can indeed occur at room temperature in the solid state. However, insufficient space may be available within the crystal lattice to allow for the large distortions obtained for the bent triplet structures, but in the solid state, distortions may not be as significant due to anchoring of the ends of the chain in the lattice. These restrictions in the movement of the chain may limit the bending to a single Cu(CN)_2 unit. A reduction in the magnitude of the distortion necessarily reduces the \(S_0 – T\) gap and shifts the emission to longer wavelengths. Finally, relaxation of the triplet through some interchain interaction similar to excimer formation in the solution phase is also a possibility in the solid state. However, as the copper centers are not always aligned well for Cu···Cu interactions, interchain interactions may be more likely to take the form of \(\mu_3\)-cyano bridging of copper centers.

Therefore, the role of the bent excited-state triplet is speculative pending further experimentation. Nevertheless, data for CuCN–L networks may provide circumstantial support for the DFT results. We have noted that three-coordinate copper centers in CuCN–L complexes luminesce at longer wavelengths than those of CuCN.\(^{3c}\) It may be theorized that the lower energy emission in CuCN–L is also the result of lower site symmetry at the Cu(I) center. Since the three-coordinate copper centers in CuCN–L are already bent (and therefore have lower local symmetry), less reorganization energy is required for emissive relaxation. We have observed in some networks containing both 2-coordinate and 3-coordinate Cu centers that the high-energy (HE) band breaks into separate components at low temperature.\(^{3c}\) Moreover, the higher energy feature in the HE band matches the emission energy of CuCN itself very closely. It follows that the observation of distinct HE and low-energy (LE) emission bands may be the result of multiple energetically accessible triplet states. Multiple states would arise through additional lower symmetry states in structurally complex CuCN–L networks, wherein copper sites are no longer symmetrically or energetically equivalent.

Conclusions

Although there have been many reports of photoluminescent behavior in solid Cu(I) compounds,\(^9\) there have been relatively few involving CuCN-based materials.\(^3, 36\) The preceding DFT study addresses a number of questions about the properties of the parent salt CuCN important to the understanding and design of CuCN-based luminescent materials. As we move from CuCN to CuCN–L networks two generalizations stand out: (1) although the excitation energy is essentially unchanged, CuCN–L emits at lower energy than does CuCN, and (2) CuCN–L materials often show distinct HE and LE emission peaks. These HE and LE emission bands have been variously ascribed to MLCT and MC excitations. In contrast, our TD-DFT studies on isolated model chains suggest that the excitation spectrum appears to arise from intrastrand \(\pi – \pi^*\) transitions resulting from excitations from occupied to unoccupied \(\pi\)-type MOs. Given the similarity in experimental excitation spectra between CuCN and CuCN–L, it appears that the CuCN excitation mechanism is not substantially altered in CuCN–L.

Luminescence emission is a more complicated matter. The behaviors of CuCN and CuCN–L are quite distinct. The present computational results suggest that a bent triplet state is responsible for the relatively high energy CuCN emission. This is an interesting conclusion since it suggests the formation of a distinct locus for emission behavior. Additional bonding at this bent copper site, leading to the exciplex and excimer formation previously noted in \([\text{Cu(CN)}_2]^+\), would thus be facilitated. Moreover, under this scenario the lower energy luminescence emission noted in lower symmetry three-coordinate CuCN centers could be due to the lower reorganization energy associated with triplet formation.
